

→ big array of data

→ chop into equal size blocks

→ one little worker per block

→ all workers run at the same time in CPU

CUDA

block 0 → 4 threads (scalars)

thread 0: $z[0] = x[0] + y[0]$

⋮

thread 4: $z[4] = x[4] + y[4]$

TRITON

block 0 → 1 program (vectors)

program (pid = 0)

$z[0:4] = x[0:4] + y[0:4]$

one vectorized op on the block

the normal way: with loop copy one by one

the GPU way: 3 workers work at the same time for 3 things

↳ give same instruction and each worker → kernel

give badge 0, 1, 2 → pid

which boxes? $= pid \times bs + [0, 1] \rightarrow$ offs
and what to put

grid → how many workers to hire

this is the whole idea
"All at the same moment"

entire point of "mask" existing is because of "cdiv"

T T T T | T T T T
0 1 2 3 | 4 5 6 7

mask = offs < n

→ is this box full or belongs to array?

tl. load → read

tl . store → write
to memory.

pid → offs → mask → load → store

EXAMPLE 1: Copy

$$\text{offs} = \text{pid} * \text{bs} + \text{tl.Orange}(0, \text{bs})$$

$$\hookrightarrow 2 \times 2 + [0,1] = [4,5]$$

$$\Rightarrow \text{so } 1, 2, 3, 4, 5, 6$$

EXAMPLE 2: Grayscaleing Image

New idea #1: memory is a flat line even for 2D img

New idea #2: with 2D data, every worker have 2 badges

position = row × width + col

Here's the unrolling, with one cell traced through it:

the Image — 3 rows × 4 columns (width = 4)

0,0	0,1	0,2	0,3
1,0	1,1	1,2	1,3
2,0	2,1	2,2	2,3

$$\text{position} = \text{row} \times \text{width} + \text{col} = 1 \times 4 + 2 = 6$$

stored in memory as one flat line:

0	1	2	3	4	5	6	7	8	9	10	11
---	---	---	---	---	---	---	---	---	---	----	----

cell (row 1, col 2) lives at slot 6 on the line

To work with 2d data, we'll build 2d offsets and masks. Here's an illustration how it works, e.g. for an 4x7 matrix and block sizes of 2 for each dimensions.

EXAMPLE 3: Mat Mul (naïve)

$\text{pid} \rightarrow \text{offs} \rightarrow (\text{load} \rightarrow \text{dot} \rightarrow \text{accumulate, repeated}) \rightarrow \text{store}$

We want to multiply the $m \times k$ -matrix **A** and the $k \times n$ -matrix **B** into the $m \times n$ -matrix **C**.

We split the computation along each of the three axes:

- along the m axis - we'll use block dimension 0 to represent this $\text{pid-m} = \text{program_id}(0)$
- along the n axis - we'll use block dimension 1 to represent this $\text{pid-n} = \text{program_id}(1)$
- along the shared k axis - this will not be represented by a block. All chunks of computation will be done in same block.

Splits along m - and n -dimensions are represented by blocks

Split along k -dimension is represented by 'phases', which are done in the same block

EXAMPLE 4: fast MatMul

With naive ordering

To compute 9 blocks of C

0	1	2	3	4	5	6	7	8

=

we need to load **9 blocks** from A

x

and **81 blocks** from B,

so **90 in total**.

With grouped ordering

To compute 9 blocks of C

0	1	2						
3	4	5						
6	7	8						

=

we need to load **27 blocks** from A

x

and **27 blocks** from B,

so **54 in total**.
